Algorithms - CheatSheet

IN BA4 - Ola Nils Anders Svensson Notes by Ali EL AZDI

This is a cheat sheet for the Algorithms midterm exam. For suggestions, contact me on Telegram ($elazdi_al$) or via EPFL email (ali.elazdi@epfl.ch).

```
\alpha a^{d} + \beta b^{d} = 1 \Rightarrow T(n) = \Theta(n^{d} \log n),

\alpha a^{d} + \beta b^{d} = 1 \Rightarrow T(n) = \Theta(n^{d} \log n),

\alpha a^{d} + \beta b^{d} > 1 \Rightarrow T(n) = \Theta(n^{p}),
                                                                                                                                                                                                            3. If \frac{a}{b^d} > 1 (or d < \log_b a), then T(n) = \Theta(n^{\log_b a}).
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    with p determined by \alpha a^p + \beta b^p = 1.
 Insertion Sort
                                                                                                                                                                                                                             Maximum Subarray Problem
           Select the key  \begin{array}{ll} \text{INSERTION-SORT}(A,n) \\ \text{Begin with the second} & \text{for } j = 2 \text{ to } n \\ \text{element (at index 1) as} & \text{key} = 4 [j] & \text{into the sorted sequence } A[1...j-1], \\ \vdots & \vdots & \vdots & \vdots & 1 \end{array} 
                                                                                                                                                                                                                            Problem: Find contiguous subarray with largest sum

1. Divide and Conquer Approach:

Divide: Split array at midpoint

\text{mid} = \lfloor (\text{low} + \text{high})/2 \rfloor

\text{retun}(\text{low}, \text{high}, \text{A}[\text{low}], \text{high})

\text{retun}(\text{low}, \text{high}, \text{A}[\text{low}])

\text{density}(\text{low}, \text{high}, \text{A}[\text{low}])

\text{density}(\text{low}, \text{high}, \text{A}[\text{low}])
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        FIND-MAX-CROSSING-SUBARRAY(A.low.mid.high)

// Find a maximum subarray of the form A[i \dots mid].

left-sum = -\infty

sum = 0

for i = mid downto low

sum = sum + A[i]

If sum > ijk^2 + sum

max - loft = i

// Find a maximum subarray of the form A[mid + 1 \dots j].

right-sum = -\infty

sum = 0

for j = mid + 1 to high

sum = sum + A[j]

If sum > right-sum

right-sum = sum

right-sum = sum

max-right = j

// Return the indices and the sum of the two subarrays.

return (max-loft, max-loft, loft-sum + right-sum)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        FIND-MAX-CROSSING-SUBARRAY (A, low, mid, high)
                                                                                                                                                                                                                                                                                                                                                                                                              if high == low
return (low, high, A[low])
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 // base case: only one element
                                                                                                                                                                                                                                                                                                                                                                                                               else mid = [(low + high)/2]

Divide: Partition each of A,B,C into four \frac{n}{2} \times \frac{n}{2} submatrices:
           Returns TRUE if the stack is empty.
Returns FALSE otherwise.
                                                                                                                                                                                                                                                                                                                                                                                                                                                          Returns TRUE if the queue is empty (Q.head = Q.tail).
                                                                                                                                                                                                                                                                                                                                                                                                                                                 1. Returns TRUE it the queue is empty (Q.neau - Q.van).
2. Returns FALSE otherwise.

Enqueue(Q, x): Time: O(1), Auxiliary Space: O(1)
1. Adds element x to the rear of queue Q.
2. Q[Q.tail] = x
3. Q.tail = Q.tail + 1 (or wrap around if using circular array)
                                                                                                                                                                                                        \begin{pmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{pmatrix} = \begin{pmatrix} A_{11} \\ A_{21} \end{pmatrix}  Conquer: Compute 7 products3. (recursively on \frac{n}{2} \times \frac{n}{2} matri-
                                                                                                                                                                                                                                                                                                                         \begin{array}{c} A_{12} \\ A_{22} \end{pmatrix} \cdot \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix}. Combine: Assemble the resulting submatrices to form C:
  Push(S, x): Time: O(1), Auxiliary Space: O(1)
1. Adds element x to the top of stack S.
2. Increments the stack pointer.
  Pop(S): Time: O(1), Auxiliary Space: O(1)
1. If Stack-Empty(S), return error "underflow".
2. Otherwise, remove and return the top element.
3. Decrements the stack pointer.
                                                                                                                                                                                                                                                                                                                           C_{11} = M_1 + M_4 - M_5 + M_7,

                               Initializing pointers at the start of each subarray.

(a) Initializing pointers at the start of each subarray.
(b) Comparing the elements pointed to, and appending the smaller one into a new array.
(c) Advancing the pointer in the subarray from which the element was chosen.
(d) Repeating this process until all elements in both subarrays are merged into the sorted array.
Merge Cost Complexity: O(n) per merge operation.
Time Complexity: O(n log n) Space Complexity: O(n)

Root is A[1] Left(i) = 2i Right(i) = 2i + 1 Parent(i) = \lfloor i/2 \rfloor

Max-Heapify (heapify subtree rooted at i)
1. Starting at the root
2. Compare A[i], A[Left(i)], A[Right(i)]
3. If necessary, swap A[i] with the largest of the two children
4. Max-Heapify the swapped child
5. Continue comparing and swapping down the heap until subtree rooted at i is max-heap Time\ Complexity:\ O(\log n)

Space

Complexity:\(O(n)\) including heap array,\(O(1)\) auxiliary

Max-Heap-Insert (insert new key into heap)
1. Increase heap size:\(A.heap-size = A.heap-size + 1 \)
2. Set the last element to negative infinity:\(A[A.heap-size] = -\infty
3. Call Max-Heap-Increase-Key to update to the correct value Time\ Complexity:\ O(\log n)

Space Complexity:\ O(\log n)

Space Complexity:\ O(n)

Max-Heap-Increase-Key (increase key at position i)
1. Ensure new key is larger than current: if key < A[i] then error all A[n] = -\infty
3. Compare with parent and swap if necessary: while i > 1 and A[Parent(i)] < A[i] = \(-\infty\)
3. Compare with pair and swap if necessary: while i > 1 and A[Parent(i)] of A[i] is a pair of the root 
                                                                                                                                                                                                                                                                                                                                                                    Queue Operations

```

If $T(n) = a T\left(\frac{n}{b}\right) + f(n)$, where $a \ge 1, b > 1$, and f(n) is asymptotically

1. Case 1: If $f(n) = O(n^{\log b} a^{-\epsilon})$ for some $\epsilon > 0$, then $T(n) = \Theta(n^{\log b} a)$.

1. Case 1: If $f(n) = O(n^{-b} \circ f)$ for some $\epsilon > 0$, then $f(n) = O(n^{-b} \circ f)$. 2. Case 2: If $f(n) = O(n^{\log b} \circ a)$, then $f(n) = O(n^{\log b} \circ a)$ for some $\epsilon > 0$, and if $a f\left(\frac{n}{b}\right) \le c f(n)$

for some c<1 and all sufficiently large n, then $T(n)=\Theta(f(n))$. Common case - if $f(n)=\Theta(n^d)$ for some exponent d:

1. If $\frac{a}{b^d} < 1$ (or $d > \log_b a$), then $T(n) = \Theta(n^d)$.

2. If $\frac{a}{b^d} = 1$ (or $d = \log_b a$), then $T(n) = \Theta(n^d \log n)$.

Akra--Bazzi:

AKPA-BAZZI: For recurrence $T(n)=\alpha\,T(a\;n)+\beta\,T(b\;n)+\Theta(n^d),$ where $\alpha,\beta>0,\;a,b\in(0,1),\;d\geq0,$ and unique p with $\alpha\,a^p+\beta\,b^p=1$ Then:

If p is not easily found, compare $\alpha a^d + \beta b^d$ with 1:

 $p>d\Rightarrow T(n)=\Theta(n^p),$ $p = d \Rightarrow T(n) = \Theta(n^{d} \log n),$

 $p < d \Rightarrow T(n) = \Theta(n^{d}).$

 $\alpha a^d + \beta b^d < 1 \Rightarrow T(n) = \Theta(n^d),$

Master Theorem

positive.

Asymptotic Notation Big-O

Big-Theta

If $\exists c>0$ and $\exists n_0>0,\ 0\leq f(n)\leq c\cdot g(n)\ \forall n\geq n_0,$ then f(n)=O(g(n)).

Big-Omega If $\exists c>0$ and $\exists n_0>0,\ 0\leq c\cdot g(n)\leq f(n)\ \forall n\geq n_0$, then $f(n)=\Omega(g(n)).$

If f(n) = O(g(n)) and $f(n) = \Omega(g(n))$, then $f(n) = \Theta(g(n))$.

Linear data structure where each node contains:
1. key/data: The value stored in the node
2. next: A pointer to the next node in the sequence
3. prev: A pointer to the previous node (in doubly linked lists)
                                                                                                                                                                                                                                                                  Optimal Binary Search Tree Problem: Construct a BST with minimum expected search cost given access probabilities Optimal-BST Algorithm: • Input: Keys K_1, \ldots, K_n, probabilities p_1, \ldots, p_n for successful searches • Optional: Probabilities q_0, \ldots, q_n for unsuccessful searches
    Longest Common Subsequence
Problem: Find the longest subsequence common to two
                                                                                                                          Print-LCS:

- Recursively trace back through direction table b

- Follow diagonal arrows and print characters

- Skip cells with up or left arrows

- Stops when reaching first row or column
     LCS-Length:
    LCS-Length:

- Build tables for length c[0...m, 0...n] and direction b[1...m, 1...n]

- Initialize first row and column to zeros

- For each cell (i,j) in the
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     List-Search (find a node with a given key)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  1. Start from the head of the linked list.
2. Traverse the list by following the next pointers.
3. Compare each node's key with the target key.
4. Return the node if the key is found.
5. Return NULL if the end of the list is reached without finding the key.
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            \operatorname{List-Search}(L,\kappa)

For each subproblem, try all possible roots and
pick the minimum cost

    Create a new node with the given key.
    Set the next pointer of the new node to point to the current head.
    If implementing a doubly linked list, set the prev pointer of the current head to the new node.
    Update the head pointer to point to the new node.
    If the list was empty, update the tail pointer as well.

                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               Time Complexity: O(1) Space Complexity: O(1)
List-Delete
(remove a node from the list)
1. Find the node to be deleted (may require traversal).
2. If the node is the head, update the head pointer to the next node of the next node to skip the node being deleted.
4. For doubly linked lists, also update the prev pointer of the next node.
5. Free the memory allocated for the deleted node.
6. Handle edge cases: empty list, deleting the only node, or deleting the tail.
Time Complexity: O(n) for finding the node, O(1) for deletion

5. x.prev = N/L

LIST-DELETE(L,X)
1. if x.prev ≠ nil
2. x.prev.next ← x.next
4. if x.next ≠ nil
5. x.next.prev ← x.prev.
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             5. x.prev = NIL
```

$$\begin{split} i &= 1 \text{ to } n - l + 1 \\ j &= i + l - 1 \\ e[i,j] &= \infty \\ w[i,j] &= w[i,j - 1] + p_j \\ \text{ for } t &= i \text{ to } j \\ t &= e[i,r - 1] + e[r + 1,j] + w[i,j] \\ e[i,j] &= t \\ \text{ mod } m[i,j] &= r \end{split}$$

Time: $O(n^2)$ for tables e, w, and rootThe algorithm computes optimal costs for all possible subtrees

return e and root
Complexity:

• Time: $O(n^3)$

Complexity:

- Time: O(mn) for two sequences of lengths m and n

quences of lengths m and n - Space: O(mn) (includes input sequences and tables) - Space can be optimized to O(m+n) if only length is needed - Print-LCS takes O(m+n)

time to reconstruct the so-lution
